25 October 2015

China’s dependence on coal is a major contributor to local and global environmental problems. In this paper we estimate the price elasticity of demand for coal in China using a panel of province-level data for 1998–2012. We find that provincial coal demand has become increasingly price elastic. As of 2012 we estimate that this elasticity was in the range –0.3 to –0.7 in point estimate terms when responses over two years are considered. The results imply that China’s coal market is becoming more suited to price-based approaches to reducing emissions. The elimination of coal consumption subsidies could reduce national coal use and related emissions by around 2%.

The research received funding from the Australia-China Research Program on Climate Change Mitigation Policy, the CAS Strategic Priority Research Program (No. XDA05150600), and the National Natural Science Foundation of China (Nos. 71322306, 71273027, 71521002).
1. Introduction

China accounts for half of global coal consumption, a share that the International Energy Agency (IEA, 2014a) expects to remain relatively stable over coming decades under current policies. The country’s coal use is a substantial contributor to local and regional environmental problems, accounting for more than one-fifth of annual global carbon dioxide (CO₂) emissions from all energy sources (IEA, 2014b). China is currently trialling carbon pricing schemes in an effort to reduce greenhouse gas emissions, and has announced a move to a national scheme. Yet relatively little evidence exists on how responsive China’s coal demand has been to coal prices in recent years, especially using sub-national data. Given the role of coal in China’s emissions profile, for emissions pricing to work well it is important that coal use is responsive to prices.

In this paper we use data on provincial coal prices and coal use to estimate the price elasticity of demand for coal in China. We construct a panel covering 30 provincial-level divisions (“provinces”) for the 15-year period 1998–2012, and control for province fixed effects and other factors possibly affecting coal demand. We use sample splitting and interaction terms to explore whether the price elasticity of coal demand has changed over time. Our results suggest that provincial coal demand is becoming increasingly price sensitive, and as of 2012 was in the order of −0.3 to −0.7 when responses over a period of two years are considered. China’s economy and coal sector have marketized over recent decades, a process that may have contributed to the increasing price elasticity of demand as prices gradually take on a greater role in rationing China’s coal consumption. The paper adds to a growing body of research using provincial-level data on energy use in China (e.g. Cattaneo et al., 2011; Du et al., 2012; Li and Leung, 2012; Ma and Oxley, 2012; Hao et al., 2015).

Coal is not a homogenous commodity. The metallurgic industry mainly uses coking coal, whereas electricity generators use thermal coal. Within any broad classification there is substantial variation in coal grades and types, and in the prices for these products. While the price elasticity of coal demand may vary for different types and uses of coal, data restrictions mean that we focus on total provincial coal use, aggregated in tonnes. An advantage of adopting a panel approach is that we can control for some unobserved characteristics of coal consumption, including the period-average quality of the coal consumed in each province.

Our finding that China’s provincial-level coal price elasticity of demand is increasing has several implications. One is that price-based approaches to reducing the environmental impacts of coal use are becoming increasingly relevant in the China context. This paper’s results are also useful for informing parameter choices in energy models.¹ We also estimate the reduction in coal use and related emissions that would result from a phase-out of coal consumption subsidies in China.

The paper is organized as follows. Section 2 provides an overview of China’s coal sector, including a brief history of its ongoing marketization. Section 3 discusses our method, and

¹ Mischke and Karlsson (2014) provide a recent review of models of China’s energy-economic system.
Section 4 describes our data. Section 5 presents our results, and we compare our estimates to earlier studies in Section 6. The final section concludes.

2. China’s coal sector
2.1 China’s coal use and emissions
China’s appetite for coal has grown at an extraordinary rate. Figure 1 shows annual coal use, aggregated in energy content terms, by China and the rest of the world for 1965–2013. In 1965, China accounted for only 8% of global coal consumption. Over the 48 years to 2013, China’s coal use increased at an average of 6.1% per annum. This has seen China’s share of global coal consumption reach around 50% (BP, 2014). Coal use in the rest of the world has grown more slowly, averaging 0.8% per year over 1965–2013. China’s growth in coal use is perhaps coming to a turning point, however: in a historic change, China’s coal consumption was relatively flat in 2014 in energy equivalent terms (data not shown; Doyle and Stanway, 2015).

Figure 1

The most rapidly growing use of coal in China has been for electricity generation. Figure 2 shows primary coal consumption by China’s electricity, manufacturing, and other sectors for 1994–2012. As of 2012 electricity generation accounted for half of all coal use in China, with manufacturing directly consuming 38%. Coal-fired electricity output expanded at an average rate of 9.3% per annum over 1971–2012. In 2012, 76% of China’s electricity generation was coal-fired, up from 70% in 1971 (IEA, 2015). Residential coal consumption, included in the “Other” category in Figure 2, has fallen as a result of factors such as the installation of central heating systems and electrification. China’s rise has involved a huge expansion of energy-hungry sectors such as the steel industry, the output of which has increased more than 30-fold over the last four decades (CEIC, 2014).

Figure 2

Coal dominates China’s CO₂ emissions. Figure 3 shows China’s total energy-based CO₂ emissions by fuel for 1971–2012. In 2012, 83% of China’s energy-based CO₂ emissions were from coal, a share that has remained quite steady since the early 1970s. 14% of China’s energy-based emissions were from oil, and only 3% from natural gas. Coal is also the primary contributor of other atmospheric emissions in China, including sulphur dioxide and particulates, and so has large health implications. Outdoor air pollution, mostly from coal, has been estimated to cause around 1.2 million deaths per year nationally (Wong, 2013).

Figure 3

Figure 4 presents China’s output price index for the mining and washing of coal, the coal price measure we use at the provincial level in our empirical estimations. The index almost tripled over the first decade of the new millennium in nominal terms, before falling in 2012 (the last year of our empirical analysis). Coal price increases outstripped the modest rise in
China’s aggregate industrial producer price index, meaning that in real terms coal prices more than doubled over the decade. The 2012 downturn in the coal price index extended into 2013, a year for which nominal coal prices were recorded as falling by around 11%. Figure 4 also shows a coal import price at Qinhuangdao port, China’s largest coal shipping port. The Qinhuangdao price is positively correlated with the coal sector’s output price index, but displays greater volatility.

Figure 4

Substantial geographical variation in per-capita coal use is shown in Figure 5. The highest reliance on coal is in China’s north, where the largest coal reserves and a large share the country’s heavy industry can be found. Southern provinces are smaller users of coal. Our method addresses persistent differences in coal dependence via the use of province fixed effects and estimates in differences.

Figure 5

2.2 Marketization of China’s coal sector
The ongoing marketization of China’s coal sector as the country continues its transition from a planned to a more market-based economy might mean that prices are now playing a more important role in rationing coal use. If so, this may have translated to an increase in the price elasticity of coal demand. In this section we provide details about the marketization process.

During 1949–1978, the production, transportation, and use of coal and other “strategic resources” were primarily allocated by the central government, and coal prices were maintained at a low level (Thomson, 2003; Xiao and Wu, 2011; Wright, 2000, 2012). In 1978, China began its policies of reform and opening up. In the subsequent years, coal continued to be priced and allocated by the government, but prices and the profit mechanism began to play a more substantial role in resource allocation.

An important step occurred in 1984–1985 with the official introduction of “dual track” pricing with separate in-plan and out-plan prices for coal and other commodities (Wright, 2000; Wang, 2007; Yang et al., 2012). A share of coal was still mandatorily priced by the government, but the remainder was able to be priced by the market. A large share of the coal produced by local township enterprises was not included in the national plan and so was priced freely. Noticeable regional price differences emerged.

In late 1993 the central government announced that coal price regulation would be abolished. While the move to market-based pricing for non-electricity consumers of coal was largely successful, electricity generators faced problems in adjusting to market prices for coal given that they continued to face tightly regulated electricity prices. In 1996 the central government returned to its role of controlling the price of a large share of the coal sold to electricity consumers.

---

2 The decline in coal prices has extended into 2014 and 2015; data not shown.
generators, with prices for “key contract” coal usually 10–30% below the market price (Wang, 2007; Yue, 2007; Ma et al., 2009; Ma and Oxley, 2012; Wright, 2012). Various government interventions to influence coal prices for the electricity sector were used, including price caps and price guidance during contract negotiations.

Since 1996, China’s government has made numerous attempts to finally end its influence over the coal prices paid by electricity generators. Yet the reform path has been tortuous: disagreements between the coal and electricity sectors and the threat of electricity shortages have repeatedly led the government to continue to arrange low prices for the electricity sector, albeit for contracts representing a generally diminishing share of coal sales (China Daily, 2007; IEA, 2009; Li, 2014).

While there has been continued central influence, it is important to note that even government-influenced coal prices are affected by market movements: they rise when supply constraints are pressing, for example (Chu et al., 2006). Compliance with government controls has also not been complete, with strategies for avoiding the trappings of low-price coal supply contracts including the levying of additional fees; supplying low-quality coal; and simply not delivering, thereby forcing electricity generators to purchase coal on the spot market (Rutkowski, 2013). There is evidence that coal and electricity prices have started to co-move (Ma and Oxley, 2011), suggesting an increasing influence of market forces.

At the end of 2007, the National Development and Reform Commission released a new Coal Industrial Policy (Zhao et al., 2012), and the coal sector has reached a new level of marketization which, while not complete, involves a greater role for market forces in allocating coal than has historically been the case (Ma and Oxley, 2012). Nevertheless, the central government has still intervened, for example by ordering a freeze on coal prices for electricity companies in 2011 to quell inflation (The Economist, 2011). As of 2012 a share of the coal supplied to electricity generators was still under government-guided contracts with below-market prices (Zhang, 2012), with the IEA (2013) estimating that coal and electricity consumption subsidies equalled $13 billion per annum.3

In late 2012 it was again announced that the central government would no longer require coal producers to enter contracts to supply quantities of “key contract” coal to electricity generators at preferential prices (Zhang, 2014). In November 2013 a blueprint for the reform was released. More broadly, in October 2015 China’s State Council announced a plan to remove price interventions in all competitive sectors by 2017, although government-administered prices will remain for some sectors such as electricity (Xinhua, 2015). The implications of China’s ongoing pricing reforms for the operation of the coal market will be of interest.

In short, there has been an increasing marketization of coal sales to the electricity sector, and it is fair to say that coal sales outside the electricity sector are quite highly marketized.

---

3 Electricity subsidies largely result from low-price coal, so we include these in our analysis.
Marketization may mean that coal users have become more sensitive to the coal price over time as prices replace planning mechanisms in determining coal allocation. Whether the price elasticity of demand has indeed increased is the focus of our empirical estimates.

3. Method

To obtain estimates of the average price elasticity of demand for coal at the provincial level in China, we start with a basic log-log demand model:

\[
\ln C_{p,t} = \beta_1 \ln P_{p,t} + \beta_2 \ln Y_{p,t} + \beta_3 t + \delta_p + \varepsilon_{p,t}
\]

where \( C \) is primary coal consumption in province \( p \) in year \( t \), \( P \) is an output price index for the mining and washing of coal deflated by the industrial producer price index, \( Y \) is real GDP, \( t \) is a linear time trend increasing from 0 in 1998 to 14 in 2012, \( \delta_p \) is province fixed effects, \( \varepsilon \) is an error term, and \( \ln \) is the natural logarithm. Our use of data on coal consumption, not production, is appropriate for a study of demand (cf. supply). We include province fixed effects to control for time-invariant factors that may influence coal demand in each province. The choice of fixed effects over random effects is supported by a Hausman test, although as a robustness check we will also present results using random effects. Results tables will show standard errors that are robust to heteroskedasticity and clustered at the province level to allow for province-specific patterns of serial correlation.

Eq. (1) is a static estimation using within-province temporal variation, an approach typically interpreted as providing short-run elasticities (Baltagi, 2008). To capture the fact that adjustments to changes in coal prices take time and that coal contracts often extend over more than one year, we also present estimations including lagged coal price terms. We use lags for years \( t-1 \) and \( t-2 \). To conserve degrees of freedom, we then move to specifications that include only the terms for year \( t \) and year \( t-2 \), as the \( t-1 \) lagged price term is not statistically significant. Using the 3rd or 4th lags provides similar results to using the 2nd lag, but further reduces sample size.

Our primary interest is whether the coal price elasticity of demand has changed over time. We hypothesize that coal demand has become more price elastic: if prices were previously less important in coal use decisions, we would expect this to be reflected in \( \beta_2 \) being less negative for earlier years of our sample than later years. We use two approaches to test our hypothesis. The first is splitting the sample into an “early” period (1998–2007) and a “late” period, which we define as 2008–2012, years during which the coal sector has exhibited its highest level of marketization to date (Ma and Oxley, 2012, p. 139). We obtain similar results if we define the “late” period as commencing in 2009 or 2010.\(^4\) Our second approach is to estimate specifications that interact our coal price terms with the time trend:

\[
\ln C_{p,t} = \beta_1 \ln P_{p,t} + \beta_2 \ln Y_{p,t} + \beta_3 t + \beta_4 \ln P_{p,t-1} + \delta_p + \varepsilon_{p,t}
\]

(2)

\[
\ln C_{p,t} = \beta_1 \ln P_{p,t} + \beta_2 \ln Y_{p,t} + \beta_3 t + \beta_4 \ln P_{p,t-1} + \beta_5 \ln P_{p,t-2} + \beta_6 \ln P_{p,t-2} + \delta_p + \varepsilon_{p,t}
\]

(3)

\(^4\) Our price elasticity of coal demand for the “late” period becomes statistically indistinguishable from zero if we extend this period back to 2007. This reflects the principal result of the paper: we only find statistical evidence that the price elasticity of demand is significantly different from zero for more recent years.
In Eq. (2), the static price elasticity in the final year of our sample (2012; \( t = 14 \)) is equal to \( \beta_1 + 14\beta_4 \). In Eq. (3), the two-year price elasticity in 2012 is equal to \( \beta_1 + \beta_5 + 14(\beta_4 + \beta_6) \). Our tables will report these elasticities and their significance levels.

In additional specifications we control for a set of time-varying factors that might influence provincial coal use. The first is the share of provincial output contributed by the secondary sector, as industrial output is likely to have a more coal-intensive input bundle. The second is the importance of state-owned enterprises in provincial economies. The third is a measure of the five-year energy conservation assignments prescribed to industrial enterprises in each province under the central Government’s 1,000 Enterprises Energy Conservation Campaign of 2006–2010 and 10,000 Enterprises Energy Conservation Campaign of 2011–2015. The fourth is a measure of retired thermal power capacity, to capture the central government’s campaign to phase out inefficient coal-fired electricity generation plants. We also control for each province’s log real gasoline price.

In a check on our results, we also employ the following specification in differences:

\[
\Delta_x \ln C_{p,t} = \gamma_0 + \gamma_1 \Delta_x \ln P_{p,t} + \gamma_2 \Delta_x \ln Y_{p,t} + \gamma_3 t + \gamma_4 \Delta_x \ln P_{p,t}^* t + \epsilon_{p,t}
\]  

(4)

where \( \gamma_2 + 14\gamma_4 \) provides an estimate of the \( x \)-year price elasticity of provincial demand for coal, evaluated in 2012. This specification allows level effects to be removed (in the differencing), provides an efficient estimation of responses that may take more than one year to be realized, and avoids unit root issues (see below). We use specifications from \( x=1 \) to \( x=5 \).

The potential endogeneity of coal prices is a concern: there may be reverse causality from demand to prices, and other variables that are correlated with provincial coal prices may lurk in the error terms of our models. If so, our estimates of the coal price elasticity of demand may be biased and inconsistent, likely causing an underestimate of the coal price elasticity (upward bias). We tried two instruments for our coal price index: 1) the log real international coal price, and 2) provincial coal reserves. Both, however, provided inadequate first-stage identification strength.\(^5\) Prior studies on China’s coal demand have also not used instrumental variable approaches.

Several factors help to mitigate concerns regarding endogeneity. First, our use of the second lag of \( \ln P \) reduces reverse causality from coal consumption to the coal price.\(^6\) Second, producer prices for coal may not always be substantially affected by provincial demand given that there are many external destinations for coal extracted in any province. Third, recent studies by Burke and Nishitateno (2013) and Lin and Zeng (2013) find that endogeneity bias does not substantially affect estimates of the price elasticity of gasoline demand, although this is not necessarily generalizable to coal. Finally, our specifications consider a variety of

\(^5\) The log international coal price remained a weak instrument even when weighted by each province’s distance to the nearest sea port or the railway freight costs from the nearest sea port. Province fixed effects, log GDP, and the time trend were included in these specifications. Several measures of international coal prices were explored.

\(^6\) We obtain similar estimates in specifications that exclude the contemporaneous price term (i.e. use only the second lag).
controls, including provincial fixed effects. We obtain similar results across our estimations, pointing to a consistent story.

An additional issue is the time-series properties of the data. Employing the panel unit root test of Im et al. (2003) with a time trend and the subtraction of cross-sectional means, we are able to reject the null hypotheses of a “unit root in every province” for both the log coal consumption and log coal price index series. This test is suited to unbalanced panels such as ours. We are not able to reject the null that every province has a unit root in log GDP. Nevertheless, our results are similar in specifications that exclude log GDP. We also find similar results using specifications based on differenced data (Table 4). The Im et al. (2003) test rejects the nulls that all provinces have a unit root for first-year differenced data for log coal consumption, the log coal price index, and log GDP. Time-series issues are therefore not likely to be materially affecting our findings.

4. Data
Our estimations use yearly provincial panel data for 1998–2012, with our panel covering 30 provincial-level divisions in Mainland China: 22 (formal) provinces, 4 municipalities (Beijing, Tianjin, Shanghai, and Chongqing), and 4 autonomous regions (Inner Mongolia, Guangxi, Ningxia, and Xinjiang). Data on coal consumption are not available for Tibet, so Tibet is excluded from our sample. Our sample includes 395 observations; it is unbalanced due to some missing data for provincial coal consumption and/or price, particularly early in the period. The main sources of data are the CEIC (2014), National Bureau of Statistics (2013, 2014), China Electricity Council (2013), and National Development and Reform Commission (2011, 2012). A full list of variable definitions and data sources is provided in the Appendix, and the dataset and code are available on the corresponding author’s website. Table 1 presents summary statistics.

Table 1 –

The output price index for the mining and washing of coal in each province is the best coal-price measure we know of for the purpose of this study. The index captures coal price movements in a way that does not rely on averaging observed coal prices across different types of coal, advantageous given that provincial data on coal consumption by coal type are not available. Directly observed data on coal prices also have coverage challenges. As Cattaneo et al. (2011) report, coal price data are not available at the provincial level. While some data are available for cities, these are patchy, and do not extend over as long a time period as the output price index.

While China’s coal extraction is dominated by Inner Mongolia and Shanxi, most provinces extract and/or wash some coal. The coal price elasticity of demand may vary by sector, but we do not have data on sectoral purchase prices. To obtain a coal price index in real terms, we deflate the nominal index by the provincial industrial

---

7 As Cattaneo et al. (2011) report, coal price data are not available at the provincial level. While some data are available for cities, these are patchy, and do not extend over as long a time period as the output price index.

8 While China’s coal extraction is dominated by Inner Mongolia and Shanxi, most provinces extract and/or wash some coal. See the Appendix for details on how we treat Shanghai.
producer price index. Results are similar using a coal price index that is not deflated or that is deflated with the provincial GDP deflator or consumer price index.

In an additional specification we use a proxy of the real coal price level (cf. index) in each province, calculated by multiplying (1) the average coal price paid by the electricity and heat sectors in each province in 2007 with (2) our time-varying index of coal prices in each province, and then deflating and logging. We calculated the average price in 2007 from China’s provincial input-output tables for 2007. Details are in the Appendix.

In addition to challenges with coal price data, there are also issues surrounding data on coal consumption in China. The existence of small, unapproved coal mines means that coal data are less precise than data for other fossil fuels (Sinton, 2001). There is also evidence that local authorities have over-reported provincial coal use to appear consistent with over-reported GDP (Ma et al., 2014). The central government’s requirements for provinces to meet energy conservation targets and to close inefficient coal-fired electricity generators has, on the other hand, provided an incentive for underreporting (Guan et al., 2012). Official data are subject to error and revision, and there are discrepancies between national and provincial figures (Liu, Z. et al., 2015; Mischke and Xiong, 2015). While we control for provincial GDP, energy conservation targets, and power plant closures, as well as other factors that might be associated with data quality (such as provincial fixed effects and a time trend), our results – like those from prior studies – need to be interpreted with serious data quality considerations in mind.

5. Results

Table 2 presents our results, with columns 1–4 providing static estimates and columns 5–9 including lagged coal price terms. The full-sample estimate in column 1 provides no evidence that provincial coal price movements are associated with provincial coal consumption, and we also find a statistically insignificant coal price elasticity in column 2 for a sample restricted to 1998–2007. Column 3 finds a coal price elasticity of –0.2 for 2008–2012, significantly different from zero at the 5% level. These estimates suggest that coal use has become more responsive to prices in recent years.

Column 4 of Table 2 estimates Eq. (2) for the full sample. The interaction between the coal price variable and the time trend is negative and strongly significant, suggesting that the provincial coal price elasticity of demand has increased in absolute value. The estimate implies that this elasticity reached –0.4 in 2012 ($\beta_1 + 14\beta_4$), significantly different from zero at the 5% level.

Column 5 of Table 2 includes the price term for years $t-1$ and $t-2$, in addition to year $t$. The $t-1$ term is statistically insignificant, while the $t-2$ term is different from zero at the 1%

---

9 The closing of many informal coal mines in recent years has perhaps reduced this problem.
significance cut-off. The overall price elasticity of demand for the full period from this estimation is –0.1, not significantly different from zero. To conserve degrees of freedom, we exclude the insignificant t–1 term from future estimations. Column 6 of Table 2 is the same as Column 5, but without the t–1 term. The coefficients on the other variables remain similar, and the mean two-year price elasticity \((\beta_1 + \beta_3)\) remains not statistically different from zero in this full-sample estimate.

Columns 7–8 of Table 2 split the sample into the early (1998–2007) and late (2008–2012) periods. We find estimates of the two-year price elasticity of coal demand of 0.0 and –0.4 respectively, with the latter different from zero at the 5% significance level. This again suggests that provincial coal demand is becoming more price elastic. Column 9 interacts the two price terms with the time trend for the full sample and finds that the two-year coal price elasticity of demand has indeed become larger, reaching –0.7 in 2012 (significant at 1%). The implied price elasticity of demand is 0.0 in 1998, –0.2 (statistically indistinguishable from zero) in 2002, and –0.4 (significant at 1%) in 2007. The point estimates of the income elasticity of coal use in Table 2 are larger than one (elastic).

In the base of Table 2 we present the static and two-year price elasticities of coal demand for two additional specifications: random effects (Specification 2); and using our log real price level measure instead of the log real price index in a pooled ordinary least squares (OLS) estimation without province fixed effects (Specification 3). The latter allows for geographical variation in coal prices as well as the temporal variation provided by the index. The random effects results are similar, while Specification 3 generally provides larger price elasticity of demand point estimates. The Specification 3 results continue to suggest that the price elasticity of coal demand has increased over time, reaching –0.7 in 2012 when responses over two years are considered (and –0.6 when only same-year responses are included). Interestingly, coal price elasticity estimates for the full and early samples are in some cases statistically significant in Specification 3, although time-invariant variables affecting provincial coal demand have not been considered in these estimates.

Cattaneo et al. (2011, p. 21) report “isolated clusters” of spatial dependence in their study of provincial coal use. As a robustness check we repeated the estimation in column 9 of Table 2 six times, each time excluding one of six regions (north; northeast; east; south-central; southwest; northwest). The results are similar to our full-sample estimates. Our results thus appear to not be driven by spatial dependence considerations within one region.

Table 3 presents fixed-effects results for estimates of Eq. (3) with additional controls. In column 2 we interact log GDP with the time trend, finding no evidence that the income elasticity of coal use has changed over time. Columns 3–8 include the secondary share of the economy, state-owned share of revenue from industrial enterprises, energy conservation requirements, retirements of thermal power capacity, and the log real gasoline price. The price elasticities from these specifications are shown in the base of the table. We find an increasing price elasticity over time in each of the estimates, as shown by the negative coefficients for the price-time interaction terms. The two-year price elasticity of coal demand,
when assessed in 2012, is statistically significant, with point estimates from −0.5 to −0.7. When assessed in 2007, these estimates range from −0.2 to −0.4. As of 2002, they were statistically inseparable from zero. For the static estimates, the year-2012 point elasticities range from −0.2 to −0.5. It makes sense that these are smaller than the two-year price elasticities because the static estimates allow less time for coal consumers to respond to price changes.

-Table 3-

The results on the controls in Table 3 are of interest.\textsuperscript{10} We find that a higher secondary share of the economy is associated with slightly more coal use, likely because industrial output is coal intensive. Specifically, a percentage-point increase in the secondary share of the economy is associated with 1% more coal consumption. The estimate in column 8 suggests that provinces more dependent on state-owned enterprises use slightly more coal. We find no significant effect of industrial energy conservation requirements or thermal plant retirements on provincial coal use. Columns 7–8 suggest that gasoline and coal are complements in China, as also reported by Ma and Oxley (2012).

Table 4 shows estimates of Eq. (4) for specifications in one-year, two-year, three-year, four-year, and five-year differences. Our sample shrinks as we move from annual to two-year differenced estimates, and continues to do so across the columns of Table 4. In one-year differences, the interaction between the coal price index measure and the time trend is negative and statistically significant at the 1% level, again indicating that the sensitivity of coal demand to coal prices has increased over time. The implied same-year coal price elasticity of demand in 2012 is −0.2, whereas it is close to zero or even positive in early years of the panel.

-Table 4-

The estimate in column 2 of Table 4 implies a two-year price elasticity of demand of −0.3 in 2012, smaller than the levels estimates (and our reason for reporting an overall point estimate range of −0.3 to −0.7). The estimate in column 3 suggests the three-year elasticity was −0.4 in 2012, although this is only distinguishable from zero at 10% significance. The estimates in columns 4–5 provide similar point estimates of the regression coefficients, but it is not possible to conclude that price changes have a significant influence on coal use in later years in these longer-differenced specifications. These estimates are for relatively small samples, however.

Altogether, the price elasticity estimates in Table 4 are consistent with our earlier results, suggesting that the two-year response of provincial coal use to provincial coal prices has

\textsuperscript{10} We obtain similar results also controlling for a measure of enterprise profits as a share of costs from CEInet (2015). An interaction term with this measure provides no evidence that the province-level coal price elasticity of demand is systematically related to province-level enterprise profitability.
become larger over time, although remains inelastic. Table 4’s income elasticities are also similar.

6. Relating the results to existing evidence
There are only a few studies of coal demand in China using sub-national data. Ma and Oxley (2012) use provincial data for 1995–2005 to estimate translog cost functions, and derive estimates of the provincial coal price elasticity of demand of −0.6, larger (in absolute value) than our estimates for those earlier years. Zhang et al. (2013) estimate a static model for 1995–2010 using coal output value divided by output volume as their measure of provincial coal prices. They surprisingly find a positive panel estimate of the price elasticity of coal demand, although also obtain an elasticity of −0.3 in cross-sectional estimates for 2010. Cattaneo et al. (2011) and Hao et al. (2015) use spatial econometric approaches to model coal use by China’s provinces, concentrating on income instead of price effects. Provincial data have been employed to model some other energy-sector issues in China, for example the relationship between GDP and CO₂ emissions (Du et al., 2012) and the determinants of energy intensity (Jiang et al., 2014). Our study appears to be the first to explore whether the price elasticity of provincial demand for coal has changed over time.

Studies for other countries and regions have also reported that demand for coal is price inelastic, with short-run estimates typically falling in the range −0.1 to −0.6 (see Table 5 of Trüby and Paulus, 2012). Coady et al. (2015) used a coal price elasticity of demand of −0.25 in their recent study of the effects of international fossil fuel subsidy reform.

Our Table 2 estimates of the income elasticity of coal demand range from 1.2–1.7. These are high, consistent with the rapid expansion of coal use in China. Note, however, that our use of a linear time trend removes the effect of secular trends in coal use per unit output over time. In specifications without a time trend, we obtain income elasticities of 0.8, similar to those
obtained by Chan and Lee (1997) and Lin et al. (2007). Other estimates of the income elasticity of coal demand by China’s provinces include 0.2 (Cattaneo et al., 2011) and 1.1 (Masih and Masih, 1996).

7. Conclusion
China has a target to reduce the CO$_2$ intensity of its economy by 40–45% from its 2005 level by 2020 and has recently announced emissions pledges for 2030. As part of the reform effort to meet these targets, China is piloting emissions trading schemes for greenhouse gases and has announced that a national emissions trading scheme covering electricity generation and several other key emitting sectors will be launched by 2017. Implementation challenges for these schemes are not negligible (Jotzo and Löschel, 2014; Auffhammer and Gong, 2015; Liu, L. et al., 2015). The relevance of our research to these developments is that, for pricing schemes to reduce emissions, it is important that coal use is responsive to prices. China’s coal sector has increasingly marketized over recent years, and we hypothesized that this may have contributed to more price-elastic coal demand.

We have utilized provincial data and obtained evidence that coal use in China is indeed becoming increasingly sensitive to coal prices. Our estimates suggest that, as of 2012, a 1% increase in coal prices typically resulted in a reduction in the quantity of coal demanded of 0.3–0.7% (point estimates), a larger effect than witnessed in earlier years. This remains an inelastic response, but nevertheless indicates that emissions pricing could bring material reductions in emissions from coal.

Our results are similar using a variety of controls and in both level and differenced regressions. Nevertheless, the reader is reminded that there are uncertainties associated with coal use and coal price data in China. There may also be important differences in the price elasticity of demand for different coal products and uses. Our results – like those from prior studies – should be interpreted as suggestive rather than definitive. Rapid changes to China’s energy sector also mean that the price elasticity of coal demand may continue to evolve. Demand for coal is also likely to need to reduce considerably if pollution reduction and decarbonisation are to be achieved. Continued research into China’s coal demand and the price elasticity of this demand will be of interest.

In addition to ongoing marketization, there are other potential explanations for why China’s provincial-level price elasticity of demand for coal is increasing. One is that recent years have seen more substitutes for coal, including nuclear power, natural gas, and renewables. A second is that the rapid increase in coal prices over much of our study period has fed into a higher coal price elasticity of demand; in general, sensitivity to proportional price changes is likely to be higher when prices are high (Burke and Nishitaten, 2013).

The IEA (2013) estimates that in 2012 China allocated $13 billion to price subsidies for the consumption of coal ($3 billion) and the use of coal for electricity generation ($10 billion). Our rough estimate is that removing these subsidies would increase average coal prices in
China by around 3%.\(^{11}\) Using a coal price elasticity of demand of \(-0.6\), this would result in around a 2% reduction in China’s annual CO\(_2\) emissions from coal. 2% is rather a lot; equal to more than three-quarters of Australia’s annual CO\(_2\) emissions from coal (IEA, 2014b). As well as providing fiscal and efficiency benefits, the elimination of coal subsidies could thus lead to a material reduction in China’s CO\(_2\) and other emissions relative to the counterfactual in which the subsidies are retained. The above calculation is consistent with Li and Lin’s (2015) estimate of a 3% reduction in China’s energy-based CO\(_2\) emissions if all fossil fuel subsidies were removed.

One ongoing challenge for China’s energy market is the lack of a flexible mechanism to allow retail electricity prices to vary with changes in input prices, including the coal price (IEA and Energy Resource Institute, 2012). Regulated electricity prices continue to place electricity generators and utilities in difficult financial positions, as they cannot easily pass cost changes through to consumers. The phase-out of consumer subsidies for coal and electricity and a move to more flexible pricing arrangements for electricity would help to further improve the efficiency of energy use in China and increase the country’s readiness for market-based approaches to reducing emissions.

\(^{11}\) We calculate the average coal price subsidy in 2012 at 24 yuan/tonne of coal by dividing the $13 billion IEA (2013) estimate of China’s consumption subsidies for coal and electricity by China’s coal consumption in 2012 (3.5 billion tonnes; CEIC, 2014), and applying the average official exchange rate for 2012 of 6.3 yuan/$US from the World Bank (2014). We then divide the average coal price subsidy by China’s year-2012 average coal contract price for power generation as reported by the Lawrence Berkeley National Laboratory (2014). This is an approximate calculation. We obtain a similar result if we use an alternative price measure, for example the FOB Qinhuangdao price for steam coal imports (Q5500K). Coal prices have fallen over 2012–2015, reducing the potential benefit of coal subsidy reform. Our estimates are for 2012.

Appendix: Variable descriptions

**Ln Coal consumption**: Natural logarithm of total primary coal consumption, in million tonnes. Source: CEIC (2014).

**Ln Real coal price index**: Natural logarithm of: the output price index for the mining and washing of coal, deflated by the provincial industrial producer price index. A coal price index for Shanghai is not available; we have used data for Zhejiang (a neighbouring province) instead. Source: National Bureau of Statistics (2013) and various provincial Statistical Yearbooks. Industrial producer price index data are from the National Bureau of Statistics (2014).

**Ln Real coal price level**: Natural logarithm of: the product of each province’s year-2007 coal price for the thermal sector and each province’s coal price index, deflated by the provincial industrial producer price index. The year-2007 coal price for the thermal sector, in yuan per tonne, is calculated by dividing (1) each province’s thermal sector’s expenditure on intermediate inputs from the coal sector and its transportation by (2) the coal consumption of the thermal sector. Two provinces (Hainan and Qinghai) are excluded from the estimations using the coal price level. The thermal sector consists of electricity and heat generation. Source: National Bureau of Statistics (2008, 2011).

**Time trend**: Linear time trend. Equal to 0 in 1998 and 14 in 2012.

**State-owned share of total revenue from industrial enterprises (%):** Revenue of state-owned and state holding industrial enterprises as a percentage of the revenue of all industrial enterprises. For 1998–2006 the variable covers all state-owned enterprises as well as all other enterprises with principal-business revenue over 5 million yuan; for 2007–2010 the variable covers all enterprises with principal-business revenue over 5 million yuan. Since 2011, the variable covers all enterprises with principal-business revenue over 20 million yuan. Source: National Bureau of Statistics (2014).

**Five-year energy conservation assignments to industry (%):** Sum of all energy conservation assignments to individual enterprises over a five-year period (1,000 Enterprises Energy Conservation Campaign of 2006–2010; 10,000 Enterprises Energy Conservation Campaign of 2011–2015) as a percentage of total energy consumption in the first year of the five-year
period (2006 or 2011). 0 for years prior to 2006 because it was only after this year that the
central government placed greater priority on energy conservation. Source: National

Post-2005 retired thermal power capacity (%): Retired thermal power capacity in megawatts
as a percentage of the start-of-year thermal capacity; = 0 for years prior to 2006 because it
was only after this year that the central government placed greater priority on energy

Ln Real gasoline price: Natural logarithm of the price for no. 93 gasoline (without lead) in the
province’s capital city, averaged across monthly averages, and deflated by the provincial
industrial producer price index. Source: CEIC (2014). Industrial producer price index data
from the National Bureau of Statistics (2014).
